Summary statement
In epithelial cells, the spectraplakin ACF7 binds to the minus-end stabilizing protein CAMSAP3 and controls its apical recruitment, while CAMSAP3 regulates non-centrosomal microtubule organization needed for the apical localization of Rab11 endosomes and the formation of the actin brush border.

Abstract
The microtubule cytoskeleton regulates cell polarity by spatially organizing membrane trafficking and signaling processes. In epithelial cells, microtubules form parallel arrays aligned along the apico-basal axis, and recent work has demonstrated that the members of CAMSAP/Patronin family control apical tethering of microtubule minus ends. Here, we show that in mammalian intestinal epithelial cells, the spectraplakin ACF7 specifically binds to CAMSAP3 and is required for the apical localization of CAMSAP3-decorated microtubule minus ends. Loss of ACF7 but not of CAMSAP3 or its homologue CAMSAP2 affected the formation of polarized epithelial cysts in 3D cultures. In short-term epithelial polarization assays, the knock-out of CAMSAP3, but not of CAMSAP2 caused microtubule re-organization into a more radial centrosomal array, redistribution of Rab11 endosomes from the apical cell surface to the pericentrosomal region and inhibition of actin brush border formation at the apical side of the cell. We conclude that ACF7 is an important regulator of apico-basal polarity in mammalian intestinal cells and that a radial centrosome-centered microtubule organization can act as an inhibitor of epithelial polarity.
**Introduction**

Microtubules regulate cell polarity by serving as rails for intracellular transport and by controlling organelle positioning and signaling. While in many types of cultured cells microtubules form a radial array, in polarized epithelial cells microtubules are arranged along the apico-basal axis, with the minus ends located at the apical side (Akhmanova and Hoogenraad, 2015; Bartolini and Gundersen, 2006; Dammermann et al., 2003). This non-centrosomal microtubule organization can be controlled by the relocalization of γ-tubulin-binding centrosomal microtubule-anchoring proteins, such as ninein, to non-centrosomal apical sites (Moss et al., 2007) and by proteins that bind microtubule minus ends independently of γ-tubulin. The most notable example of the latter are the members of calmodulin-regulated spectrin-associated protein (CAMSAP)/Patronin family, which can recognize and decorate free microtubule minus ends and protect non-centrosomal microtubules from depolymerization (Goodwin and Vale, 2010; Hendershott and Vale, 2014; Jiang et al., 2014; Tanaka et al., 2012). Recent work in worms demonstrated that a ninein homologue and Patronin can act both redundantly and non-redundantly in organizing non-centrosomal arrays in different cell types (Wang et al., 2015).

In mammalian cells, the minus-end binding protein CAMSAP3 (also known as Nezha or Marshalin) was initially shown to interact with components of adherens junctions and anchor microtubule minus ends at these sites (Meng et al., 2008). CAMSAP3 is also very abundant in supporting cells of the organ of Corti, a specialized type of epithelial cells with extremely dense microtubule bundles that are anchored at centrosomal and non-centrosomal microtubule-organizing centers at the cell cortex (Takahashi et al., 2016; Zheng et al., 2013). Similar to other CAMSAP/Patronin family members, CAMSAP3 has a C-terminal conserved domain, the CKK, as well as several coiled coil regions and an N-terminal calponin homology (CH) domain, the function of which is currently unknown (Akhmanova and Hoogenraad, 2015; Baines et al., 2009). Through the CKK domain and the adjacent positively charged microtubule-binding regions, CAMSAP3, as well as its homologue CAMSAP2 recognize and decorate polymerizing microtubule minus ends, forming stretches of stabilized microtubule lattice that can serve as “seeds” for non-centrosomal microtubule outgrowth (Jiang et al., 2014). Recent work showed that CAMSAP3 is a major factor in organizing apico-basal microtubule arrays in enterocytes, where it strongly localizes to the apical cell cortex and tethers microtubule minus ends (Toya et al., 2016). Mice homozygous for the C-terminal truncation of CAMSAP3, in which the CKK domain is lost, were viable
but showed increased lethality at early postnatal stages (Toya et al., 2016). Intestinal epithelial cells of these mice could still polarize and form a normal brush border, in spite of the fact that the microtubules were disorganized, and the nuclei and Golgi membranes mispositioned (Toya et al., 2016). Experiments in Caco-2 cells, a human intestinal cancer cell line, demonstrated that the first coiled coil region of CAMSAP3, which was previously shown to bind to spectrin in CAMSAP1 (King et al., 2014), is involved in recruitment of CAMSAP3-bound microtubule minus ends to the apical side (Toya et al., 2016). Whether this localization indeed depends on spectrin or some other proteins was not determined.

Here, we set out to investigate the mechanism of CAMSAP3 recruitment to the apical side of epithelial cells. We found that CAMSAP3, but not CAMSAP2 interacts with the spectraplakin ACF7 (also known as MACF1, (Karakesisoglou et al., 2000; Kodama et al., 2003; Wu et al., 2008)), and that ACF7 depletion leads to the release of CAMSAP3-decorated microtubule stretches from the apical cell surface. ACF7, CAMSAP2 and CAMSAP3 were not essential for the distribution of early cell polarity markers in 2D cultures; however, loss of ACF7 though not of the two CAMSAPs affected the formation of epithelial cysts in 3D cultures, indicating that ACF7 plays a more profound role in epithelial polarity than the CAMSAPs. Loss of CAMSAP3 led to more centrosome-centered microtubule organization, and this affected the organization of the actin cytoskeleton at the apical side of the cell, likely due to mislocalization of Rab11-positive recycling endosomes, which are a major player in apical polarity and brush border formation in intestinal cells (Bryant et al., 2010; Dhekne et al., 2014; Knowles et al., 2015; Overeem et al., 2015; Sobajima et al., 2014). Taken together, our study identifies ACF7 as an important regulator of apico-basal polarity in mammalian intestinal cells and demonstrates the importance of non-centrosomal microtubule organization for efficient epithelial cell polarization.
Results

Visualization of localization and dynamics of CAMSAP3 in polarized epithelial cells using a GFP knock-in cells

To facilitate visualization of CAMSAP3 in Caco-2 cells, we have generated a homozygous knock-in line in which the endogenous CAMSAP3 protein was tagged with GFP (Fig. 1A). In agreement with previous publications (Meng et al., 2008; Tanaka et al., 2012; Toya et al., 2016), in this cell line CAMSAP3-GFP localized to microtubule ends, colocalized with endogenous CAMSAP2 and was concentrated at the apical side of polarized Caco-2 monolayers (Fig. 1B-D). Upon microtubule depolymerization by nocodazole treatment no apical CAMSAP3 stretches were detected, indicating that the apical recruitment of CAMSAP3 strongly depends on the presence of microtubules (Fig. 1E). We next used Fluorescence Recovery After Photobleaching (FRAP) assays to investigate the turnover of CAMSAP3-GFP at the apical side of polarized Caco-2 monolayers. We found that in one day old Caco-2 monolayers, a ~75% recovery of CAMSAP3-GFP signals at the apical surface occurred within ~15 min (Fig. 1F, G). This recovery was associated with movements of unbleached CAMSAP3-GFP-labeled microtubule minus ends into the photobleached area (Fig. 1F, H). Interestingly, ~15 min after photobleaching in 5 day-old monolayers, the CAMSAP3-GFP signal at the apical surface recovered only to ~40% (Fig. 1F, G). The mobility of CAMSAP3-GFP stretches in older cultures was much lower (Fig. 1H), indicating that the apical cytoskeleton undergoes maturation on a scale of several days, resulting in immobilization of CAMSAP3 stretches.

When Caco-2 cells were cultured in Matrigel, they formed cysts, as described previously (Jaffe et al., 2008). Already at the two-cell stage, GFP-CAMSAP3 colocalized with the apical markers such as atypical protein kinase C (aPKC) and the area of enhanced actin accumulation, which was located at the membrane interface between the two daughter cells, as shown before (Jaffe et al., 2008) (Fig. 1I). After 4 days in 3D culture, GFP-CAMSAP3 strongly accumulated at the apical side (Fig. 1J). In such polarized cysts microtubules were aligned along the apico-basal axis (Fig. 1K).

We never observed any accumulation of GFP-CAMSAP3 at the cell-cell junctions either in 2D or 3D cultures, which is in line with the observations in mouse intestine but contradicts the data previously obtained by immunostaining of CAMSAP3 in Caco-2 cells (Meng et al., 2008; Toya et al., 2016). Our data are thus in full agreement with the role of CAMSAP3 in apical microtubule organization but provide no support for CAMSAP3 function at the adherens junctions.
**ACF7 binds to CAMSAP3 and participates in its apical recruitment**

We reasoned that the capture and stable association of CAMSAP3 stretches at the apical surface is caused by the presence of a binding partner. To identify CAMSAP3-interacting proteins, we performed streptavidin pull down assays from HEK293T cells co-expressing Biotinylation (Bio) and GFP-tagged CAMSAP3 and the biotin ligase BirA and analyzed the isolated proteins by mass spectrometry (Jiang et al., 2014). The highest hit in this screen was the spectraplakin ACF7 (Fig. 2A), while no peptides derived from spectrin, which was previously reported to bind to CAMSAP1 (King et al., 2014), were found. Whether this was due to the absence of appropriate spectrin isoforms in HEK293T cells, the biochemical procedure used or the lack of interaction between CAMSAP3 and spectrin is not clear.

Antibody staining showed co-localization of GFP-CAMSAP3 with the puncta of endogenous ACF7 at the apical side of Caco-2 monolayers (Fig. 2B). However, in contrast to CAMSAP3, which was only localized apically, ACF7 was spread throughout the cytoplasm (Fig. 2D). As an alternative model of enterocyte polarity, we used the LS174T:W4 cell line, in which the activation of LKB1 kinase by doxycycline-induced expression of the adapter protein STRAD is sufficient to induce polarization and formation of microvilli on one side of the cell in the absence of cell-cell contacts (Baas et al., 2004). In doxycycline-treated LS174T:W4 cells, both endogenous and GFP-tagged CAMSAP3 colocalized with endogenous ACF7 beneath the polarized regions of actin enrichment (Fig. 2C), supporting complex formation between CAMSAP3 and ACF7.

We next investigated the interaction between CAMSAP3 and ACF7 biochemically. ACF7 is a very large protein (~5000 amino acids) containing N-terminal actin-binding CH domains, a plakin domain, 30 spectrin repeats, EF-hand motifs that could mediate calcium binding, a microtubule-binding GAS2-related domain and the EB1-binding SxIP motif (Karakesisoglou et al., 2000; Kodama et al., 2003; Wu et al., 2008) (Fig. 2E). Since the full-length ACF7 is difficult to efficiently express in cells, we have generated GFP-tagged ACF7 fragments covering the whole ACF7 protein. We performed streptavidin pull down assays from HEK293T cells co-expressing these fragments together with biotin ligase BirA and CAMSAP2 or CAMSAP3 tagged with mCherry and the biotinylation tag (Bio-mCherry), or just the Bio-mCherry protein as a negative control. We found that CAMSAP3, but not CAMSAP2 specifically bound to the ACF7 fragment encompassing spectrin repeats 20-26 (fragment ACF7_5, Fig. 2F). Deletion mapping further showed that the coiled coil region 1
(CC1) of CAMSAP3, which was previously implicated in the apical localization of the protein (Toya et al., 2016), was essential for this interaction (Fig. 2G).

The binding between CAMSAP3 and ACF7 was confirmed by colocalization experiments in HeLa cells. Overexpression of CAMSAP3 and CAMSAP2 caused strong bundling of microtubules, and CAMSAP3, but not CAMSAP2 could specifically recruit ACF7 fragment 5 to these microtubule bundles (Fig. 2H). Furthermore, we found that endogenous ACF7 was recruited to microtubule bundles induced by overexpression of full-length CAMSAP3 and the CAMSAP3 deletion mutant missing the CH domain, but not the CAMSAP3 deletion mutants missing the CC1 region (Fig. S1). Taken together, these data indicate that CAMSAP3 and ACF7 interact with each other and can cooperate in binding to microtubules. Deletion mapping showed that the CC1 region of CAMSAP3 and a specific spectrin repeat region of ACF7 are required for the interaction.

We next investigated whether ACF7 participates in the apical recruitment of CAMSAP3. ACF7 was depleted with two different siRNAs, and the efficiency of depletion was confirmed by immunofluorescence staining and real time PCR (Fig. 3A-C). Although actin enrichment was still observed at the apical side of ACF7-depleted Caco-2 monolayers, both the apical localization as well as the total number of CAMSAP3-GFP stretches was very strongly reduced, indicating that ACF7 regulates the localization, as well as the formation or stability of CAMSAP3-decorated microtubule stretches (Fig. 3D, E). In contrast, other early polarity markers, such as ezrin, aPKC and Zonula occludens (ZO)-1 were still localized apically in 2D cultures of ACF7-depleted cells (Fig. 3D, S2A). Also the height of polarized monolayers was not significantly affected in the absence of ACF7 (Fig. S2B). Further, in line with the fact that ACF7 depletion reduced the abundance of CAMSAP3-decorated microtubule stretches, we found an increase, albeit a mild one, in the number of centrosomal microtubules, indicating that ACF7 contributes to some extent to the maintenance of a non-centrosomal microtubule network (Fig. S2C, D).

To further address the effect of ACF7 knockdown, cells were cultured in Matrigel in 3D. To accelerate lumen formation in Caco-2 cysts in order to make 3D analysis compatible with a transient protein depletion protocol, we used dense Caco-2 3D cultures, and after the initial cyst formation treated them with cholera toxin, which strongly stimulates lumen formation by inducing cAMP signaling (Jaffe et al., 2008). In these conditions, we found a clear, well-formed or mildly disorganized lumen in ~75% of cysts treated with control siRNAs, but only in ~10% of cysts treated with ACF7 siRNAs, where cysts completely lacking the lumen were prevalent (Fig. 3F, G). Analysis of early (3-4 cell) 3D cultures
showed that while the apical polarity markers localized to intercellular junctions in control cells, as described previously (Jaffe et al., 2008), they were mislocalized in ACF7 knockdown cells (Fig. 3H).

We conclude that while ACF7 depletion does not cause mislocalization of all polarity markers in 2D cultures, it does lead to the loss of apical localization of CAMSAP3. When embedded in a 3D matrix, the distribution of all investigated polarity markers and cyst formation were strongly affected by ACF7 depletion, indicating that distinct mechanisms with differential sensitivity to ACF7 levels control the ability of cells to polarize in 2D and 3D.

**CAMSAP3 knockout leads to Rab11 mislocalization and inhibition of apical actin brush border formation**

We next set out to address the effects of the loss of CAMSAP2 and CAMSAP3 on epithelial polarity. We used CAMSAP3-GFP knock-in cells to generate Caco-2 lines lacking either CAMSAP2 or CAMSAP3 (Fig. 4A, B). Apical CAMSAP3-GFP signals were unperturbed in CAMSAP2 knockout cells, while in CAMSAP3 knockout cells, CAMSAP2 stretches became longer, as described previously (Tanaka et al., 2012) (Fig. 4A). CAMSAP-decorated microtubule stretches are generated by microtubule polymerization from the minus end, and the stretches formed in the presence of CAMSAP3 and CAMSAP2 are likely to be shorter than those formed in the presence of CAMSAP2 alone, because CAMSAP3 is a more efficient inhibitor of microtubule minus-end growth than CAMSAP2 (Jiang et al., 2014). Microtubule organization was not visibly changed in CAMSAP2 knockout cells, but a more centrosome-centered array was observed in CAMSAP3 knockout cells, in line with a previous study (Tanaka et al., 2012) (Fig. 4C, D).

Next, we analyzed polarity in CAMSAP2 and CAMSAP3 knockout clones. In 2D cultures, junctional ZO-1 and E-cadherin as well as the early markers of apical polarity aPKC and ezrin were not perturbed (Fig. S3A, B). When cultured in 3D, two out of three CAMSAP2 knockout clones and three out of three CAMSAP3 knockout clones formed morphologically normal cysts (Fig. S3C, D). Since two CAMSAP2 knockout lines could form morphologically normal cysts, we think that the morphological abnormalities in the third clone were due to secondary mutations. This conclusion was confirmed by siRNA-mediated depletion of CAMSAP2, CAMSAP3 or both CAMSAPs simultaneously (Fig. S3E). In addition, CAMSAP2 and CAMSAP3 knockout clones showed no defects in the recruitment of apical markers aPKC and ZO-1 in early 3D cysts (Fig. S3F). We conclude that
CAMSAP2 and CAMSAP3 are not required for the formation of luminized 3D cysts, indicating that the strongly affected cyst formation in ACF7-depleted cells is unlikely to be due to CAMSAP3 mislocalization.

We then focused on late markers of epithelial polarity associated with the ability of the cells to form a brush border. Apical accumulation of actin and the phosphorylated form of ezrin (pERM), an actin-binding protein important for the formation of brush border (Dhekne et al., 2014; Overeem et al., 2015; Viswanatha et al., 2012) was not affected in CAMSAP2 knockout cells (Fig. 4E, F, S3A), even though the same cell line showed abnormalities in cyst morphology in 3D (Fig. S3C, D, CAMSAP2 KO #1). This result indicates that the ability of cells to form 3D cysts and to localize actin regulators does not necessarily correlate.

Strikingly, in CAMSAP3 knockout cells, the apical accumulation of actin and phospho-ezrin was concentrated around the cell-cell junctions and reduced in the central part of the cell (Fig. 4E, F, S3A). Previous work showed that during brush border formation, the apical actin cytoskeleton is strongly regulated by signaling and/or trafficking processes dependent on the apical accumulation of Rab11-positive recycling endosomes (Dhekne et al., 2014; Knowles et al., 2015; Overeem et al., 2015; Sobajima et al., 2014). We analyzed the distribution of Rab11 endosomes using cells stably transfected with a construct for doxycyclin-inducible expression of dTomato-Rab11. Strikingly, while in control and CAMSAP2 knockout cells Rab11 endosomes were distributed under the apical surface, in CAMSAP3 knockout cells they displayed a single focus of accumulation, which coincided with the centrosome (Fig. 4G, H, S3G). In fact, the fluorescence intensity of the Rab11 clusters in CAMSAP3 knockout cells appeared to be ~5 fold higher than the fluorescence intensity of apically localized Rab11 vesicles in control cells revealing a very strong clustering of endosomes (Fig. S3G). This result was confirmed in cells, in which CAMSAP3 was depleted using siRNA: in these cells, the formation of a single centrally located Rab11 cluster strongly correlated with the efficiency of CAMSAP3 knockdown (Fig. 4I). We also analyzed Rab11 in ACF7 knockdown cells and found that the endosomes were equally distributed over the cell indicating defects in the apical targeting (Fig. S3G). However, actin still accumulated at the apical surface of ACF7-depleted cells (Fig.3D), suggesting that clustering of Rab11 endosomes in the middle part of the cell is more deleterious for actin organization than their random distribution.

Our data support the notion that the localization of Rab11 endosomes strongly correlates with the position of microtubule minus ends, in line with the idea that it is controlled by cytoplasmic dynein (Horgan et al., 2010; Khanal et al., 2016; Riggs et al., 2016; Sobajima et al., 2014).
When the microtubule array becomes more radial, Rab11 endosomes accumulate in the central part of the cell, and the formation of apical actin-rich structures is inhibited.

**Discussion**

In this study, we showed that the spectraplakin ACF7 is a binding partner of CAMSAP3 and that it is required for regulating the abundance and apical localization of CAMSAP3 stretches. While this paper was in preparation, the *Drosophila* homologues of CAMSAP3 and ACF7, Patronin and Shortstop (Shot) were demonstrated to be present in the same apical complex and cooperate with each other, as well as an apical form of spectrin, in organizing apico-basal microtubule arrays in fly epithelia (Khanal et al., 2016) and in early fly embryos (Nashchekin et al., 2016). These findings are also consistent with earlier work in flies, which demonstrated the importance of Shot for microtubule minus end organization during tubulogenesis of the embryonic salivary glands (Booth et al., 2014). ACF7 appears to act upstream of CAMSAP3 as a cortical recruitment factor, but, since it has a microtubule-interacting domain, it likely also synergizes with CAMSAP3 to some extent for microtubule binding and stabilization. We note that the accumulation of CAMSAP3 at the apical cortex occurred in the form of microtubule stretches and thus depended on the presence of intact microtubules. This is similar to the recruitment of CAMSAP2 to the Golgi membranes, where binding of CAMSAP2-decorated microtubule minus ends but not of the cytosolic CAMSAP2 was observed (Wu et al., 2016). It is possible that the presence of multiple CAMSAP molecules on the same microtubule is required for efficient binding to intracellular structures such as the Golgi and the actin-rich cortex by increasing avidity.

Since ACF7 does not show an exclusively apical localization in Caco-2 cells, an additional pathway insuring tethering of CAMSAP3 stretches specifically to the apical surface must exist. It is possible that, similar to flies, a specific apical isoform of spectrin might be involved; this would mean that the same region of CAMSAP3, the CC1, mediates apical localization by binding to two different proteins. Alternatively, some signaling pathway restricting CAMSAP3 binding to microtubules to the apical cell side might be involved. Interesting in this respect is our observation that CAMSAP3 stretches become less mobile during monolayer maturation, suggesting that as epithelial cells differentiate, more numerous connections between these stretches and the cortical cytoskeleton are formed, or the cortical cytoskeleton itself becomes less dynamic. It is also important to note that 3D cyst analysis showed that ACF7 depletion has a stronger impact on cell polarity than the
CAMSAP loss, indicating that ACF7 performs additional, CAMSAP-independent functions during epithelial polarization.

Furthermore, our data showed that the knockout of CAMSAP3 affected apical actin organization, likely because the more centrosomal microtubule system in CAMSAP3 knockout cells prevented apical accumulation of Rab11 endosomes. How can these results be reconciled with the presence of a normal brush border in mice expressing nonfunctional CAMSAP3 (Toya et al., 2016)? The most likely explanation is the gradual centrosome inactivation observed during long-term differentiation of epithelial cells. In line with this idea, in CAMSAP3 knockout mice, microtubules in epithelial cells became disorganized but did not form a radial pattern (Toya et al., 2016). A disorganized non-centrosomal array is likely to delay but not block apical localization of Rab11 endosomes or other, yet unknown polarity factors that are transported towards microtubule minus ends. In contrast, the presence of a centrosome seems to act in a dominant negative fashion, by sequestering these factors in the central part of the cell. In line with this idea, actin accumulation at the apical side was inhibited more strongly in CAMSAP3 knockout, in which Rab11 endosomes were clustered, than in ACF7 knockdown, in which the endosomes were distributed throughout the cell. These data suggest that although the centrosome can promote cell polarization in certain conditions (Bornens, 2012), in epithelial cells it acts as a polarity inhibitor and its microtubule-anchoring activity must be suppressed to allow the cells to efficiently complete their polarization program.
Materials and Methods

Cell culture and transfection
Caco-2 cells were obtained from A. Yap (University of Queensland, Australia) (Ratheesh et al., 2012) and cultured in DMEM supplemented with 10% fetal calf serum (FCS). LS174:T4 cells (Baas et al., 2004) were obtained from J. L. Bos (UMC Utrecht, The Netherlands) and cultured in RPMI supplemented with 10% FCS. HEK293T cells were obtained from ATCC and cultured in DMEM supplemented with 10% FCS. The cell lines were routinely checked for mycoplasma contamination using LT07-518 Mycoalert assay (Lonza). The identity of the cell lines was monitored by immunofluorescence-satining-based analysis with multiple markers. To grow a polarized monolayer of epithelial cells, Caco-2 cells were cultured for 5 days after reaching a fully confluent monolayer. 3D cultures of Caco-2 cells were performed by seeding cells on top (lumen formation assay) or within (3D immunofluorescence staining) 9.7 mg/ml Matrigel (Corning). One day after seeding cells were treated with 100 ng/ml Cholera Toxin (Sigma-Aldrich).

FuGENE 6 (Promega) was used to transfect Caco-2 and LS174:T4 cells with plasmids for CRISPR/Cas9 knock-in/knockout constructs and immunofluorescence. Polyethylenimine (PEI, Polysciences) was used to transfect HEK293T cells for streptavidin pull-down assays. HiPerFect (Qiagen) was used to transfect Caco-2 cells with siRNAs at 20nM. Corresponding experiments were performed 72 hours after siRNA transfection.

Streptavidin pull-down assays, Western blotting and mass spectrometry
Streptavidin pull-down and Western blotting were performed as described previously (Jiang et al., 2014). Samples were prepared from pull-down assays of biotinylated proteins from extracts of transfected HEK293T cells using streptavidin beads as described previously (Jiang et al., 2014) and were resuspended in 10% formic acid (FA) / 5% DMSO and were analyzed with an Agilent 1290 Infinity (Agilent Technologies) LC, operating in reverse-phase (C18) mode, coupled to a TripleTOF 5600 (AB Sciex). MS spectra (350–1,250 m/z) were acquired in high-resolution mode (R > 30,000), whereas MS2 in high-sensitivity mode (R > 15 000). Raw files were processed using Proteome Discoverer 1.4 (version 1.4.0.288, Thermo Scientific, Bremen, Germany). The database search was performed using Mascot (version 2.4.1, Matrix Science, UK) against a Swiss-Prot database (taxonomy human). Carbamidomethylation of cysteines was set as a fixed modification and oxidation of methionine was set as a variable modification. Trypsin was specified as enzyme and up to two miss cleavages were allowed. Data filtering was performed using percolator, resulting in
1% false discovery rate (FDR). Additional filters were; search engine rank 1 peptides and ion score >20.

**Generation of Caco-2 knock-in/knockout lines**

Caco-2 CAMSAP3-GFP knock-in en CAMSAP knockout lines were generated by using CRISPR-Cas9 technology (Ran et al., 2013). The Caco-2 CAMSAP3-GFP knock-in line was generated by transfecting the cells with the pSpCas9(BB)-2A-Puro (PX459) vector (Addgene, #62988) bearing the appropriate targeting sequence (5’-ACCGCCCGGTTGGGCTATT-3’) and the donor plasmid. Caco-2 CAMSAP knockout cell lines were generated by transfecting the cells with PX459 vector bearing appropriate targeting sequences (CAMSAP2: 5’-CATGATCGATACCCCTACATGA-3’; CAMSAP3: 5’-GTACGATTTCGCGGCCA-3’).

To establish clonal stable knock-in and knockout lines, cells were subjected to selection with 20 µg/ml puromycin for 3 days. After selection, cells were allowed to recover in normal medium for 5 days, and the efficiency of knock-in or knockout was checked by immunofluorescence staining. Depending on the efficiency, 20-100 individual clones were isolated and characterized by immunofluorescence staining.

**Protein domain prediction, constructs and siRNAs**

Protein domains were predicted using the web-based simple modular architecture research tool (SMART) (Letunic et al., 2015; Schultz et al., 1998). Full length ACF7 was purchased from Promega Kazusa Genome Technologies (pFN21AE0600). ACF7 constructs were amplified by PCR and cloned into pEGFP-C2 (Clontech). Bio-mCherry-CAMSAP2, bio-mCherry-CAMSAP3 and GFP-CAMSAP3 have been described previously (Jiang et al., 2014). Deletion mutants were cloned by PCR based strategies.

Gibson assembly was used to assemble pUC19 based CAMSAP3-GFP knock-in donor plasmid. Primers used to amplify the 5’ homology arm were: 5’-CCTTGGCCCCTCTGCACATA-3’ and 5’-TTTGGGGGTGCCGCCGCC-3’. Primers used to amplify the 3’ homology arm were: 5’-CCCCACCCGGGGCGGTCCA-3’ and 5’-TTAGTCCCTAAGCCTGGGAAGC-3’.

pSIN-TRE-rTA-IREs-Hygro-iLID-dTomato-Rab11 was constructed from pSIN-TRE-rTA-IREs-Puro (kindly provided by B. Bouchet) by replacing the puromycin resistance cassette with the hygromycin resistance cassette from pCDNA5-FRT-TO (Invitrogen) and encodes amino acids 2-216 human Rab11A (derived from GFP-Rab11 WT,
a gift from R. Pagano; Addgene plasmid #12674), N-terminally fused to the light-sensitive dimerization module iLID (derived from pLL7.0:Venus-iLID-Mito, a gift from B. Kuhlman; Addgene plasmid #60413) and dTomato.

siRNAs targeting the following sequences: ACF7 #1: 5’-TTGCAGCAGGTAAGGAC-3’; ACF7 #2: 5’-CCAAAGTGACTTGGAAGGAT-3’ (Drabek et al., 2006); CAMSAP2: 5’-GTACTGGATAATAAGGTA-3’ (Jiang et al., 2014); CAMSAP3: 5’-GCATTCTGGAGGAAATTGA-3’ and Luciferase control 5’-CGTACGCGGAATACTTCGA-3’ (Dambournet et al., 2011) were purchased from Sigma-Aldrich.

Antibodies, drugs and chemicals

Rat monoclonal antibody against tyrosinated α-tubulin (YL1/2) was purchased from Abcam (#ab6160). Mouse polyclonal antibody against ACF7 was purchased from Abnova (#H00023499-A01). Mouse monoclonal antibodies against the following proteins were used: CAMSAP3 (#SAB4200415) and γ-tubulin (#T5326) (Sigma-Aldrich); Ku80 (#611360), ZO-1 (#610966), E-cadherin (#610181) and ezrin (#610602) (BD Biosciences). Rabbit polyclonal antibodies against the following proteins were used: GFP (#ab290, Abcam); CAMSAP2 (#NBP1-21402 Novus, #17880-1-AP Proteintech); aPKC (#H00023499-A01, Santa Cruz); Actin (#20-33) and CEP135 (#SAB4503685) (Sigma-Aldrich); pERM (#3141, Cell Signaling); E-cadherin (A. Yap, University of Queensland, Australia). Alexa Fluor 405- (#A-31553, A-31556), Alexa Fluor 488- (#A27023, #A-11034), Alexa Fluor 594- (#A-11032, #R37117, #A-11007) and Alexa Fluor 647- (#A-21235) conjugated goat antibodies against mouse, rabbit and rat were purchased from Life Technologies. For Western blotting, IRDye 800CW-conjugated goat antibody against mouse and rabbit IgG (#P/N 925-32210, #P/N 925-32211) and IRDye 680LT-conjugated goat antibody against mouse and rabbit IgG (#P/N 925-68020, #P/N 925-68021) were purchased from Li-Cor Biosciences.

Alexa Fluor 594-conjugated phalloidin was purchased from Life Technologies (#A12381). Doxycycline was purchased from Sigma-Aldrich and used at a concentration of 1 µg/ml. Nocodazole was purchased from Sigma-Aldrich and used at a concentration of 10 µM. Cells were treated with nocodazole for 2 hours prior to fixation.
**Lentiviral infection and cell line selection**

Lentivirus packaging was performed by MaxPEI-based co-transfection of HEK293T cells with psPAX2, pMD2.G and the lentiviral vector pSIN-TRE-rtTA-IRES-Hygro-iLID-dTomato-RAB11. Supernatant of packaging cells was harvested up to 72 hours of transfection, 0.45 µm-filtered and incubated with a PEG 6000-based precipitation solution overnight at 4°C. After precipitation, virus was concentrated up to 100X by centrifugation and dissolution in 1X phosphate buffered saline (PBS). Target cells were incubated for 4 hours in complete medium supplemented with 8 µg/ml polybrene before infection. To establish clonal Caco-2 stable lines carrying doxycycline-inducible dTomato-Rab11, medium was replaced 24-48 hours after infection and 100 µg/ml hygromycin (Invitrogen) was added.

**Immunofluorescence staining of fixed samples**

For immunofluorescent staining of 2D cultures, cells were fixed with either 4% PFA for 20 min at room temperature (ezrin, CEP135, pERM, Phalloidin) or -20°C MeOH for 10 min (α-tubulin, CAMSAP2, aPKC, ZO-1, ACF7, CAMSAP3, Actin, E-cadherin, γ-tubulin) followed by permeabilization with 0.2% Triton X-100 for 2 min. Next, samples were blocked with 1% BSA diluted in 1X phosphate-buffered saline (PBS) supplemented with 0.05% Tween-20 for 45 min and sequentially incubated with primary antibodies for 1 hr and fluorescently labeled secondary antibodies for 45 min. Finally, samples were washed, dried and mounted in DAPI containing Vectashield (Vector laboratories).

For immunofluorescence staining of 3D cultures, cells were fixed with 4% PFA for 20 min at room temperature, rinsed with 1X PBS:Glycine (10X stock: 38.00 g NaCl, 9.38 g Na₂HPO₄, 2.07 g NaH₂PO₄, 37.50 g Glycine in 500 ml milliQ water, pH 7.4) followed by permeabilization with 0.5% Triton X-100 in 1X PBS:Glycine for 20 min. Next, samples were blocked with 1% BSA diluted in 1X IF wash (10X stock: 38.00 g NaCl, 9.38 g Na₂HPO₄, 2.07 g NaH₂PO₄, 2.5 g NaN₂, 10 ml Triton X-100, 2.5 ml Tween-20 in 500 ml milliQ water, pH 7.4) for 45 min and sequentially incubated with primary antibodies for 2 hr at 37°C and fluorescently labeled secondary antibodies for 1.5 hr at room temperature. Finally, samples were washed and mounted in DAPI containing Vectashield.
**Microscopy and image analysis**

2D confluent monolayers and 3D cultures were imaged by confocal fluorescence illumination on a Nikon Eclipse Ti microscope equipped with a perfect focus system (PFS, Nikon), a spinning disk-based confocal scanner unit (CSU-X1-A1, Yokogawa), an Evolve 512 EMCCD camera (Photometrics) attached to a 2.0X intermediate lens (Edmund Optics), a super high pressure mercury lamp (C-SHG1, Nikon), a Roper Scientific custom-made set of Stradus 405 nm (100 mW, Vortran), Calypso 491 nm (100 mW, Cobolt) and Jive 561 nm (100 mW, Cobolt) lasers, a set of ET-BFP2, ET-EGFP, ET-mCherry and ET-EGFP-mCherry filters (Chroma) for widefield fluorescence observation, a set of ET460/50m, ET525/50m or ET535/30m (green), ET630/75m (red) and ET-EGFP/mCherry filters (Chroma) for spinning disk-based confocal imaging and a motorized stage MS-2000-XYZ with Piezo Top Plate (ASI). The microscope setup was controlled by MetaMorph 7.7.11.0. Images were acquired using Plan Fluor 10x NA 0.3 air, Plan Fluor 20x M I NA 0.75 oil, Plan Apochromat λ 60x NA 1.4 oil and Plan Apo VC 60x NA 1.4 oil objectives. This system was also used for fluorescent recovery after photobleaching (FRAP) experiments using the iLas2 system (Roper Scientific).

Z-series images of 2D confluent layer were acquired using a 0.1 µm-step confocal based scan. Side views were reconstructed by projecting maximum fluorescent intensities of 50 x 0.11 µm side view slices. Apical/basal polarity index was determined by using side views as described above in the following equation: \( \frac{F_a}{F_b} - 1 \) in which \( F_a \) is the fluorescent intensity in the upper 1/3 of the side view corrected for the area and \( F_b \) is the fluorescent intensity in the lower 2/3 of the side view corrected for the area. For presentation, images were adjusted for brightness using ImageJ 1.50b. FRAP measurements were performed by bleaching a 8.8 µm diameter circle in the apical side of a cell monolayer followed by 15 min imaging with a frame interval of 10 sec.

Phase contrast images were acquired on a Nikon Ti equipped with a perfect focus system (PFS, Nikon), a super high pressure mercury lamp (C-SHG1, Nikon), Lambda SC Smart Shutter controllers (Sutter), a Plan Apochromat DM 20x NA 0.75 (Ph2) or a Plan Fluor DLL 10x NA 0.3 (Ph1), a ET-mCherry filter (Chroma), a CoolSNAP HQ² CCD camera (Photometrics), a motorized stage MS-2000-XYZ with Piezo Top Plate (ASI) and a stage top incubator INUG2E-ZILCSD-DV (Tokai Hit) for 37°C/5% CO2 incubation. The microscope setup was controlled by the open source microscopy software Micro-manager.
To determine protein knockdown efficiency by immunofluorescence staining, cells were imaged on a Nikon Eclipse 80i upright microscope equipped with a CoolSNAP HQ2 CCD camera (Photometrics), an Intensilight C-HGFI precentered fiber illuminator (Nikon), ET-DAPI, ET-EGFP and ET-mCherry filters (Chroma), controlled by Nikon NIS Br software and using a Plan Apo VC 100x NA 1.4 oil, Plan Apo VC 60x NA 1.4 oil or a Plan Fluor 20x MI NA 0.75 oil objective (Nikon). For knockdown efficiency tests, fluorescence intensity was measured per cell and corrected for the cell surface area using ImageJ 1.50b.

Microtubule organization in CAMSAP knockout lines was imaged by confocal fluorescence illumination on a Leica TCS SP8 STED3X SMD FLIM Super Resolution and confocal microscope equipped with Adaptive Focus Control, a filter free Spectral Leica SP detector and HyD detector, a 405 nm DMOD and a fully tunable supercontinuum white laser (470 to 670 nm). Images were acquired using a HC PL APO Cs2 100x/1.40 oil objective. Z-series were acquired using respectively 0.16 µm (Control) and 0.22 µm (CAMSAP2 and CAMSAP3 knockout) step confocal-based scan. Images are presented as maximum projections and adjusted for brightness using ImageJ 1.50b.

RT-PCR and qPCR analysis
Total RNA was extracted from Caco-2 cells using Trizol reagent (Thermo Fisher Scientific) and used as a template for reverse transcription with random hexamer primers (Thermo Fisher Scientific). After DNase treatment (Thermo Fisher Scientific), cDNA was submitted to quantitative real time PCR using Sybregreen technology (Applied Biosystems) on a ViiA7 apparatus (Applied Biosystems). Two ACF7 and two reference gene (HPRT1 and GAPDH) primer pairs were used to quantify ACF7 relative expression following siRNA transfection using the ΔΔCt method. Primer sequences were as followed:

ACF7 #1: 5’-GGTCCCTCTCAGGCATCAAAC-3’, 5’-AGTTTCACCTGTCGCTGCTT-3’
ACF7 #2: 5’-TGCACTCATTCACCGATACC-3’, 5’-CCCAGTCTTTCTGCCACTTC-3’
HPRT1: 5’-TGCAGACTTTGCTTTTCTTGGTCAGG-3’, 5’-CCAACACTTCTGCGGTGGTCTTTTCA-3’
GAPDH: 5’-CTTGCCTCTCTGCTCTCTGTTGCG-3’, 5’-ACCAGGCAGCCCAATACGACCAAAAT-3’.
Statistical analysis
All experiments were conducted at least twice. Statistical analysis was performed using GraphPad Prism 5.
