Summary Statement
Using a novel system to identify cell growth regulators, we have discovered a number of factors that activate growth in cells in which growth is developmentally switched off.

Abstract
Cellular growth control is important for all living organisms but experimental investigation into this problem is difficult because of the complex range of growth regulatory mechanisms. We have used the fission yeast *Schizosaccharomyces pombe* to identify potential master regulators of growth. The *S. pombe pat1*<sup>ts</sup>*mei4Δ* strain enters the meiotic developmental program at restrictive temperature, but arrests in meiotic G2 phase as *mei4<sup>+</sup>* is essential for meiotic progression. These cells do not grow, even in an abundance of nutrients. To identify regulators of growth that can reverse this growth arrest, we introduced an ORFeome plasmid library into the *pat1<sup>ts</sup>mei4Δ* strain. Eight genes when overexpressed, promoted cell growth; 2 of these were core RNA polymerase subunits, and one was *sck2<sup>+</sup>*. An S6 kinase, thought to contribute to TORC1 signalling. *Sck2* had the greatest effect on cell growth and we also show that it significantly increases cellular transcription rate. These findings indicate for the first time that global transcriptional control mediated through S6 kinase signalling is central to cellular growth control.
Introduction

The regulation of cell growth is important for all living organisms. The highly conserved kinase TOR (target of rapamycin) has been shown to play a major role in cell growth through the coordination of numerous cellular processes in response to stress and nutritional changes (Loewith and Hall 2011). Although some downstream effectors have been identified in yeast and mammals, it is still quite unclear how a positive TOR signal is transduced into cell growth regulation leading to cell mass accumulation. Furthermore, there is a paucity of assays that measure directly cell growth *per se*; in particular, a system in which cell growth is switched on in an otherwise non-growing cell has been lacking. Establishing such an assay in a system in which TOR is conserved would illuminate the presently unknown strategies used by cells to activate their growth programme.

The rod-shaped fission yeast, *Schizosaccharomyces pombe*, doubles in mass and length during the cell cycle, generating two daughters of equal size after medial division. Newly divided daughter cells grow from only a single end of the cell, until part way through the cell cycle, when the other end of the cell starts to grow. Bipolar growth continues until cells enter mitosis, at which point, the cells are held at a constant length until nuclear division completes and septation initiates. These restraints over cellular growth during different phases of the cell cycle imply that there is global regulation of cellular growth and hint at the existence of cell growth master regulators (Mitchison 2003; Navarro et al. 2012).

Growth regulation of fission yeast is responsive to nutrient availability. Tor2 is the catalytic component of the TORC1 complex and is essential for growth, whereas Tor1, of the TORC2 complex, regulates growth during stress and starvation responses. Some of the downstream effectors of TOR signalling are known; however, how TORC1 activity leads mechanistically to the regulation of cell growth is not clear. One of the best characterised downstream effectors of TORC1 is the S6 kinase (S6K1 in human and Sch9 in budding yeast), which phosphorylates multiple substrates involved in protein translation, transcription, and cellular metabolism (Jorgensen et al. 2004; Urban et al. 2007; Huber et al. 2009; Lee et al. 2009; Wei and Zheng 2009). Three S6 kinases in *S. pombe*, Sck1, Sck2 and Psk1, are thought to act downstream of TOR signalling, but the specific functions of each kinase are not well understood (Jin et al. 1995; Fujita and Yamamoto 1998; Nakashima et al. 2012). Deletion of *sck2+* renders cells resistant to TORC1 inhibition and leads to decreased polysome-to-monosome ratio suggesting an effect on translation; however, whether this effect is direct or indirect is not clear. Sck2 also influences cell size at division as *sck2+*
deletion results in smaller cells and overexpression of sck2+ promotes cell lengthening (Rallis et al. 2014).

Nutrient depletion is the trigger for fission yeast to enter the sexual developmental programme, and this process involves both the TOR and MAPK pathways (reviewed in Yanagida et al. 2011; Broach 2012). When nitrogen is absent, cell growth is turned off, triggering two progressive cell divisions without intervening growth phases to yield small cells arrested in G1. If cells of the opposite mating type are present in the population, cells will sexually differentiate and progress through pre-meiotic S-phase and enter meiotic G2, before undertaking meiosis I and II. Inhibition or inactivation of Tor2 in mitotically dividing cells induces a phenotype reminiscent of nitrogen starvation, where cells divide without growth, and arrest in G1 (Uritani et al. 2006), and Tor2 downregulation is necessary for cells to enter the sexual developmental programme (Alvarez and Moreno 2006). Deletion of tor1+ renders cells defective in the nitrogen-starvation response, which then leads to a defect in mating (Kawai et al. 2001; Weisman and Choder 2001).

In fission yeast, meiosis can be triggered experimentally without nutrient depletion by inhibition of Pat1 kinase (Iino and Yamamoto 1985; Nurse 1985). Shifting cells harbouring a temperature-sensitive pat1 allele, pat1-114, to the restrictive temperature leads to the activation of Mei2, an RNA-binding protein essential for premeiotic DNA synthesis, and entry into meiosis I (Yamamoto 1996). Deletion of mei4+ in pat1-114 cells prevents entry into meiosis I and II, and causes cells to arrest in meiotic G2 at the restrictive temperature (Borgne et al. 2002). Here we show that pat1-114 mei4Δ cells do not grow in this meiotic G2 arrest, in contrast to cells in mitotic G2 arrest, where cell growth and elongation continues. Importantly, this meiotic down-regulation of growth occurs even in the presence of abundant nutrients. This suggests that the interruption of growth that occurs during meiosis is not simply a result of nutrient limitation, but is an actively controlled cellular process. This situation therefore provides a model system in which to identify controls acting on cell growth. Based on this system, we have screened a genetic overexpression library in pat1-114 mei4Δ cells undergoing this developmental switch to identify genes able to override the observed down-regulation of growth.
Results

*Developmental growth arrest in fission yeast*

Incubating cells harbouring the temperature-sensitive *pat1-114* allele at the restrictive temperature of 34°C drives cells into the meiotic developmental programme. Deletion of *mei4* blocks progression into the meiotic divisions, leading to an arrest in meiotic G2 (Figure 1A). We examined the cell cycle profile of *pat1-114 mei4Δ* cells that were synchronised by nitrogen starvation prior to meiotic activation. Upon temperature shift, cells exited G1, and by 3 h most were blocked in G2 (Supplementary Fig 1A) (Borgne et al. 2002). Average cell length extended from 6.5 μm to 8 μm during the first 4 h after the temperature shift and then remained constant at 8μm for up to 10 h, in the G2 block (Figure 1B). We repeated the experiment in complete EMM media which contains a nitrogen source and found that cells attained a cell length of only ~12 μm (by 6 hours at 34°C) and then ceased growth (see cells in Figure 1C). Cell viability was examined by a colony formation assay, carried out at each time point of the 34°C arrest by plating cells at 25°C. We found that G2 arrested cells showed no decrease in viability up to 6 hours after temperature shift although viability did gradually decrease over the following 18 hours compared with wild type cells (Supplementary Figure 1B). These data indicate that the *pat1-114 mei4Δ* strain undergoes a developmental switch-off of cell growth even in the presence of nutrients.

*Genome-wide screen for regulators of cell growth*

We used this system to carry out a screen to identify genes that can circumvent the growth arrest. We expected that such genes might encode master regulators of cell growth that can override the signalling process that inhibits growth. The Riken ORFeome plasmid library, which covers 96% of fission yeast protein-coding genes and pseudogenes, was used to identify genes that when overexpressed could reinitiate growth during the meiotic arrest (Matsuyama 2006). Plasmid pools from the library harbouring 4910 clones under the thiamine-repressible nmt1 promoter were transformed into the *pat1-114 mei4Δ* strain and transformants were screened. The screening procedure is summarised in Figure 2A and consisted of an initial microscopic visual screen, followed by cell length measurements of candidate gene overexpression strains in the meiotic G2 arrest (see Materials and Methods). The screening procedure was carried out at both permissive and restrictive temperatures to
rule out genes that cause mitotic cell-cycle delay when overexpressed; such strains would be elongated when they entered the meiotic arrest. We identified 40 transformants that exhibited cell size elongation in the \textit{pat1-114 mei4Δ} arrest. The transformed plasmids were recovered from these strains, sequenced, and integrated into the \textit{leu1} locus of the \textit{pat1-114 mei4Δ} strain in order to obtain stable expression (Matsuyama et al. 2004). Twenty five genes were found to cause cell size elongation specifically during the \textit{pat1-114 mei4Δ} meiotic G2 arrest (Supplementary Table 1, Supplementary Figure 2).

\textbf{Analysis of putative growth regulators}

Of the 25 genes identified, 8 attained a cell length 30\% longer than the control strain and were studied further (Figure 2B). Three of these genes do not currently have experimentally confirmed biological roles in \textit{S. pombe} (Table 1). The five remaining genes include \textit{mde7}^+, which encodes a RNA-binding protein with a role in meiosis and \textit{sec26}^+, which encodes a protein involved in vesicle-mediated transport. More informatively, 2 of the 5 characterised genes are RNA polymerase subunits, suggesting that transcription could play a role in cell growth reactivation in our system. Additionally, the candidate gene that gave the greatest cell elongation phenotype was \textit{sck2}^+, which encodes a serine/threonine kinase and is an orthologue of Sch9, the S6 kinase downstream of TOR in budding yeast (Fujita and Yamamoto 1998).

\textit{Sck2 – activator of cell growth and transcription}

The cell length increase caused by Sck2 overexpression in the \textit{pat1-114 mei4Δ} strain at the restrictive temperature is shown in Figure 3A, 3B, and Supplementary Figure 3A. To rule out the possibility that the effects of Sck2 overexpression were due to cells returning from a meiotic to a mitotic programme, we examined the expression of genes expressed in meiosis, \textit{bqt1}^+, \textit{mcp6}^+ and \textit{mcp7}^+, in both control and Sck2 overexpressing cells. The expression of these genes were similarly induced in the control and Sck2 overexpressing strains at restrictive temperature (Supplementary Figure 3B), indicating the Sck2 overexpressing cells were still within the meiotic developmental programme.

Given that two of the cell growth promoting genes were RNA polymerase subunits, we proceeded to test whether transcription could be involved in Sck2-induced continuation of cellular growth. We measured transcription rate by assaying total RNA transcription through $[^3H]$-adenine pulse labelling using conditions that mostly reflect RNA synthesis rather than RNA turnover (Fraser 1975). In meiotic arrest, transcription rate was greater in Sck2
overexpressing cells than in the control strain (Figure 4A), indicating that transcription is more active in the Sck2 overexpressing strain. Transcription rate normally varies with cell size and Zhurinsky et al. (2010) reported that cells within a 2-fold size-range of the wild type maintain similar transcription rates per protein (Zhurinsky et al. 2010). Sck2 overexpressing cells were 43% larger than control cells at 34°C (Figure 4B), but the transcription rate was elevated 5-fold (Figure 4C). The protein amount per cell increased 68% in Sck2 overexpressing cells (Figure 4D) and total RNA levels were 43% higher in Sck2 overexpressing cells (Figure 4E), but the transcription rate per protein was 3-fold higher than control cells (Figure 4F), indicating that transcription rate was significantly induced by Sck2 overexpression. Additionally, we treated Sck2 overexpressing cells at 34°C with a transcription inhibitor, thiolutin or 1-10 phenanthroline, and assayed cellular growth. In the presence of either drug, cell lengthening was inhibited, indicating that transcription is required for Sck2-dependent cell growth (Supplementary Figure 4A). Together these data suggest that Sck2 has a rate limiting role for transcription, which in turn has a role in regulating cellular growth during meiotic growth arrest.

We next investigated whether other putative S6 kinases could initiate cell growth when overexpressed and found that overexpression of Sck1 or Psk1 led to only a small increase in cell growth at 34°C, and that of Gad8 had no effect (Supplementary Figure 5). This indicates that Sck2 is the most potent of the TORC1 effectors in promoting cell growth.

Given the transcription rate increase observed in Sck2 overexpressing cells, we re-examined our initial screen hits. As mentioned above, 2 of our 8 final growth-promoting candidates were RNA polymerase (Rpb) subunits, Rpb11 and Rpb6. Additionally, amongst our second tier candidates, which increased cell length by 8-30%, we found Rpb5 and Srb4, a subunit of the Mediator complex (a coactivator of RNA polymerase II-dependent transcription (Spahr et al. 2000)). These observations prompted us to consider the role of other RNA polymerase subunits in our system. To this end, we integrated into the pat1-114 mei4Δ strain, and overexpressed, the twelve Rpb subunits, as well as Iwr1, which imports RNA polymerase II into the nucleus. We noted cell length increases in all but Rpb8 and Rpb4 (Figure 5), giving further support to the idea that control of RNA transcription regulates global cellular growth.
Discussion

This study has uncovered regulators of cell growth that are independent of nutrient availability. Eight genes were found which, when overexpressed, cause cells to grow significantly during meiotic arrest and are therefore potentially rate limiting for cellular growth.

The presence of genes involved in transcription (3 DNA-directed RNA polymerase subunits and the RNA polymerase II transcriptional cofactor \textit{srb4}) amongst our primary screen candidates suggests that transcription rate is limiting for cell growth. Zhurinsky \textit{et al.} (2010) proposed that there is a global cellular control that regulates the overall transcription rate in the cell and coordinates the transcription rates of the majority of genes (Zhurinsky \textit{et al.} 2010). It was proposed that there is a factor (or factors) limiting gene transcription, whose level is determined by the protein content of the cell. Transcription machinery components such as RNA polymerase were suggested as potential candidates for this (Zhurinsky \textit{et al.} 2010). Furthermore, RNA polymerase subunits Rpb1, Rpb2, Rpb3, Rpb6, Rpb7 and Rpb9 have all been reported to be haploinsufficient for cellular fitness (Kim \textit{et al.} 2010), further suggesting that RNA polymerase subunits themselves may be limiting for cell growth.

The strongest cell elongation phenotype observed in the screen was due to overexpression of Sck2. As Sck2 is thought to act downstream of TORC1, a positive growth regulator, it is notable that we did not pick up Tor1 or Tor2 in our screen. This could be because Tor activity cannot be overcome by simple overexpression. We observed only moderate cell lengthening when other TORC1 targets, Sck1 and Psk1, were overexpressed, suggesting that Sck2 has a more prominent role in cellular growth control. We further demonstrate that Sck2 is rate limiting for transcription because overexpression of Sck2 increases the transcription rate per protein in meiotic G2 arrest. The established role of Sch9 in modulating RNA pol II-dependent expression of ribosomal proteins, together with its role in Pol I and Pol III dependent transcription, positions Sch9 in budding yeast as a key coordinator of ribosome biogenesis and protein synthesis through transcription regulation (Jorgensen \textit{et al.} 2004; Johnson 2010; Du \textit{et al.} 2012). Sck2 may be carrying out analogous functions to Sch9 by enhancing transcription, which subsequently stimulates ribosome biogenesis, which may facilitate the positive effect of Sck2 on cell growth. Sck2 has been previously placed in the Tor signalling pathway but this is the first report that it can regulate overall cell growth.
We set out to identify factors involved in global cell growth regulation in a context where nutrients are not limiting and the cell cycle is arrested. Our finding that, in addition to Sck2, numerous identified genes are involved in transcription indicates that global regulation of transcription itself is a key step in cellular growth control. In a growing budding yeast cell, 60% of total transcription is devoted to ribosomal RNA and 50% of RNA polymerase II transcription is devoted to ribosomal protein genes (Warner 1999). An increase in overall transcription would therefore favour an increase in the synthesis of ribosomal components, which would be necessary to promote an increase in cell mass through increased protein translation capacity. Our study has revealed a central role for global transcription mediated through S6 protein kinase signalling on cellular growth control.

Materials and methods

Strains and growth conditions
S. pombe media and methods used are described in Moreno et al. (Moreno et al. 1991). Strains used are listed in Table S1. Initial screening experiments were carried out in agar minimal media supplemented with 0.15 mg/ml L-histidine, L-leucine and adenine (EMM-U) with 5 μg/ml thiamine (+T) or without (-T) at 25°C or 34°C. Phenotype confirmation experiments were carried out in liquid minimal media supplemented with 0.15 mg/ml L-histidine, adenine and uridine (EMM-L) (+/-T) at 25°C or 34°C. RNA content, protein content and transcription rate experiments were carried out in minimal media (EMM) without supplements at 25°C or 34°C.

Screen for cell growth
The Riken ORFeome plasmid collection was transformed into pat1-114 mei4::kan ura4-D18 strains and the resultant transformants screened for suppression of the growth arrest. A pat1-114 mei4::kan ura4-D18 strain transformed with a plasmid containing the gene SPBC1711.15c (pDual-YFH1c-SPBC1711.15c) was used as a control strain (A01). This gene is annotated as an uncharacterised Schizosaccharomyces pombe specific protein and its deletion has no obvious effect on cell size, growth or population doubling time (Kim et al. 2010). The 52 plates of recombinant bacteria from the Riken ORFeome collection were inoculated using a pin-tool into forty five 96-well (2 ml capacity) plates containing 1 ml of LB+ 50 μg/ml ampicillin and incubated at 37°C for 16 h with shaking. Each plate was
combined and plasmids prepared using the Qiaprep spin miniprep kit (Qiagen). Each pooled plasmid preparation was transformed into the pat1-114 mei4::kan ura4-D18 strain and selected for the ability to grow on EMM-U+T at 25°C. For each transformation, 1000 colonies were patched on EMM-U+T at 25°C in order to represent 99% of plasmids within the pool (probability assumed using formula described in (Zilsel et al. 1992)). Plates were replica plated to one EMM-U+T plate and two EMM-U-T plates. After 24 h growth, one of the EMM-U plates was moved to 34°C for a further 16 h. Transformants were then visually screened for those elongated on the plate at 34°C, but not on the plates at 25°C when compared with the control. The visual screen for cell size phenotypes was carried out using a Zeiss Axioskop 40 microscope equipped with a 20×/0.4 NA objective and an additional 1.8× magnification. From this first screen, we selected ~500 different transformed strains for a second screen in liquid culture, in which growth conditions were better controlled. Candidate transformants were grown as above but in individual flasks containing 15 ml of EMM-U-T media at 25°C and 34°C, and cell size was screened following 16 h after the temperature shift to 34°C (and when the culture at 25°C was growing in exponential phase). Cell wall and septum were stained with calcofluor (Sigma) and cells were observed with a Zeiss Axioskop microscope, equipped with a 63×/1.4 NA objective and a Zeiss AxioCam MRm camera. Images were captured for transformed strains that appeared to be longer than the control strain and the length of arrested and dividing cells measured from captured images. 40 transformed strains were confirmed to be elongated compared to the control strain.

For these strains, cells were grown in liquid culture and plasmids recovered using the QIAprep® Spin Miniprep Kit (Qiagen, protocol adapted by Michael Jones, Chugai Institute for Molecular Medicine, Ibaraki, Japan). The recovered plasmid was sequenced using the following primer: 5’- GGAAGAGGAATCCTGGCA – 3’. The location of the plasmid within the Riken library was also checked against the pool number used for the initial transformation. The plasmids identified were prepared individually from the Riken ORFeome, digested with the restriction enzyme NotI and integrated by transformation into the strain pat1-114 mei4::nat ura4 D18 leu1-32 at the leu1 locus, as described for the pDUAL vector series (Matsuyama et al. 2004). Candidate transformants were grown in individual flasks containing 15 ml of EMM-L media at 25°C, and half the culture moved to 34°C for 6 h. Cell length measurements confirmed 24 candidate genes that cause cell elongation in the meiotic arrest without affecting cell length in mitotically dividing cells.
Cell length measurements and statistical methods

Cell length was measured from pictures of live calcofluor-stained cells using the PointPicker plug-in of ImageJ (National Institutes of Health). Average cell length values were determined from at least 100 cells (whole imaged population). In box-and-whisker plots, boxes are delimited by the first quartile, median and third quartile, and whiskers mark maximum and minimum values within a 10-90% range of the data. Values outside this range are displayed as individual dots.

Transcription rate assays

For transcription rate analysis, 3.5 μCi of [³H]-adenine (21 μCi/nmol, Amersham) and 7.4 μM unlabelled adenine were added to 1 ml culture aliquots grown in EMM medium and samples were incubated for 10 min at respective temperatures noted in the text and figures. The reaction was stopped by the addition of 10 ml ice-cold 10% TCA containing 0.74 mM adenine. Precipitated RNA was collected by filtering through Durapore nitrocellulose filters (Millipore), followed by 6 washes with 10% TCA and one wash with ethanol. Filters were dried and their radioactivity determined in a LS6000IC scintillation counter (Beckman) using UltimaGold scintillation liquid (PerkinElmer).
Protein and RNA content
Cells were harvested by centrifugation, frozen in liquid nitrogen and washed twice in Milli-Q-H₂O before determination of protein or RNA contents. Cellular protein contents were determined after overnight lysis in 1 M NaOH 1% Triton X-100 using BioRad DC protein assay kit. Cellular RNA content was determined from the OD at 260 nm following precipitation in 10% ice-cold TCA and two extractions in 5% TCA at 90°C for 15 min.

Cell number measurements
Cell number was determined using a Sysmex XP-300.

RNA isolation, RT-PCR and qPCR.
RNA was isolated using hot phenol extraction (Schmitt et al. 1990). RNA was treated with RNase-free DNase and 1 μg RNA used as template in first strand synthesis by Superscript III (Invitrogen) primed with oligo (dT)₂₀. 1 μl cDNA was then used for qPCR with the following primers: For mcp6:  jg317, CAATCACTTTTCAGAGTC and jg320, CAGGTTCACACACAGAAACAG. For mcp7:  jg321, CGGAAAAGATTGGCACTAGC and jg324, GTTGCAGATCGTCAATCC. For sck2:  jg341, CGCTGATAACACACAACAAC and jg343, GTCCATATCGGATGTTGTCC. For bqt1: jg305, CCCAAATCGCGATTACTC and jg308, CGTTTGACTAAAGGCACACTG.

Flow cytometry
DNA content per cell was determined from 10⁴ cells that were fixed with 70% (v/v) ethanol and then washed with 1 ml 50 mM sodium citrate. Cells were resuspended in 0.5 ml 50 mM sodium citrate containing 0.1 mg/ml RNase A and incubated at 37°C overnight. DNA was stained with 2 μg/ml propidium iodide and samples were sonicated before analysis in a BD FACSCalibur instrument.
Acknowledgments
We thank members of the Nurse lab for discussion and critical reading of the manuscript and J. Zhurinsky for experimental advice.

Competing Interests
We have no competing interests to declare.

Funding Sources
This work was supported by the Francis Crick Institute which receives its core funding from Cancer Research UK (FC01121), the UK Medical Research Council (FC01121), and the Wellcome Trust (FC01121). In addition this work was supported by Wellcome Trust Grant [grant number 093917], The Breast Cancer Research Foundation and The Rockefeller University.

Author Contributions
PN and LW conceived and designed experiments. LW performed experiments, except that presented in Supplementary Figure 3, which was performed by JG. LW, JG and PN wrote and edited the manuscript.

Supplementary Figure 1. Cell viability. A. FACS was performed on cells in Figure 1B for the first 4 time points. B. *patl-114 mei4::natMX6 ura4 D18 leu1-32* and 972 *h- (WT)* cells were grown exponentially in yeast extract complex media supplemented with 0.15 mg/ml L-histidine, L-leucine, adenine and uridine (YE4S) at 25°C before moving to 34°C at time 0. 100 cells were removed from each culture and plated onto YE4S plates at the times indicated and incubated at 25°C for 3 days when colony number was counted and compared to cell number plated to give % viability.
Supplementary Figure 2. Cell length measurements.

Cell length measurements for candidate colonies resulting from the secondary screening in liquid culture following integration of the gene. Boxes are delimited by the first quartile, median and third quartile, and whiskers mark maximum and minimum values within a 10-90% range of the data. Values outside this range are displayed as individual dots. Candidate strains were grown in EMM-U exponential culture for 24 h at 25°C and a further 6 h at 34°C. n>100 cells per strain were analysed.
Supplementary Figure 3.

![Histogram showing relative expression for bqt1, mcp6, mcp7.](image)
Supplementary Figure 3. Sck2 overexpression in meiotic arrest.

A. Mean cell length of A01 and Sck2 overexpressing cells after temperature shift to 34°C at time 0. \( n > 50 \) cells per timepoint. Error bars represent SEM. B. Cells overexpressing the control gene, A01, or \( sck2^+ \) (Sck2) were induced for 22 hours at 25°C, then shifted to 34°C for 6 hours. RNA was prepared from cells at the 6 hour time point, reverse transcribed and analysed by qPCR for the genes shown on the X-axis.

Supplementary Figure 4. Inhibition of transcription. A. Inhibition of transcription prevents cell elongation in sck2+ overexpressing cells. Cells were grown in EMM at 25°C for 22 h to induce gene expression before an additional 6 h growth at 25°C or 34°C. 15 µg/ml Thiolutin or vehicle alone or 100 µg/ml 1,10-Phenanthroline or vehicle alone were added to cells at the same time as the temperature shift. Cell length measurements at 6 h are shown. Boxes are delimited by the first quartile, median and third quartile, and whiskers mark maximum and minimum values within a 10-90% range of the data. Values outside this range are displayed as individual dots. More than 100 cells per condition were analysed. B. Cells growing at 25°C were treated with 15 µg/ml thiolutin (Thio) or vehicle alone (DMSO) or 100 µg/ml 1,10-Phenanthroline (1,10-Phe) or vehicle alone (EtOH) for 10 min before pulsing cells with [3H]-adenine for 20 min. [3H]-adenine incorporation into total RNA per cell was determined.
Supplementary Figure 5. Sck2 paralogues.

Cell length measurements for cells grown at 25°C for 22 hours to induce indicated gene expression, then shifted to 34°C to induce meiotic entry. Cell length after 6 hours at restrictive temperature is shown. Boxes are delimited by the first quartile, median and third quartile, and whiskers mark maximum and minimum values within a 10-90% range of the data. Values outside this range are displayed as individual dots. n>100 cells per strain were analysed.
